

## MONITORING SYSTEM

### BACKGROUND OF THE INVENTION

The present invention relates to an image processing  
5 technique for synthesizing images, taken by multiple cameras,  
through various types of processing including deformation and  
integration. More particularly, the present invention re-  
lates to a technique effectively applicable to a monitoring  
system as an aid for vehicle driving operations, for example.

10 Recently, car-mounted display devices have been more and  
more popularized and the prices of video capturing devices,  
including video cameras, have been reduced drastically. Re-  
flecting such tendencies, a system usable as a safety check  
aid for a vehicle driver by allowing him or her to monitor  
15 the vehicle's surroundings using video cameras is now avail-  
able at a reasonable price and is being popularized now.

A system as disclosed in Japanese Patent Application No.  
10-217261 is an exemplary vehicle surrounding monitoring sys-  
tem of that type. Specifically, the system combines together  
20 images that have been taken by multiple cameras mounted on a  
vehicle to produce a synthesized image, which looks as if the  
vehicle were seen from a virtual viewpoint located over the  
vehicle, and then presents the virtual image to the driver.

FIG. 19 illustrates an exemplary configuration for a sys-  
25 tem of that type. As shown in FIG. 19, the system includes:

camera section 40 made up of multiple cameras 401; image processing section 50 coupled to the camera section 40 via transmission lines 45; and display device 60. The image processing section 50 includes: buffer memories 501 associated with the  
5 respective cameras 401; mapping table 502 describing a relationship between a synthesized image that should look as such to a virtual viewpoint and the images actually taken by the cameras 401; and image synthesizer 503. Each of the cameras 401 included in the camera section 40 outputs an image signal  
10 on a field-by-field or frame-by-frame basis. The image signal output is transmitted through associated one of the transmission lines 45 and then stored on associated one of the buffer memories 501. By reference to the data stored on the mapping table 502, the image synthesizer 503 combines together the im-  
15 age signals, read out from the buffer memories 501, to produce a synthesized image and present it on the display device 60. By looking at the synthesized image produced by the system shown in FIG. 19, the user (i.e., the driver of a vehicle) can know an exact positional relationship between his or her own  
20 vehicle and the vehicle's surroundings without taking the actual positions of the cameras into consideration. Accordingly, this system allows the driver to park his or her vehicle much more safely, for example.

The system of this type, however, has the following drawbacks.  
25

TOP SECRET

As shown in FIG. 19, each of the transmission lines 45 is associated with one of the cameras 401. That is to say, the same number of transmission lines 45 as that of the cameras 401 should connect the cameras 401 to the image processing section 50. Normally, the cameras 401 are mounted at various positions of a vehicle to produce a synthesized image representing the vehicle's surroundings. Accordingly, the vehicle should be wired with the transmission lines 45 here and there. As a result, it takes too much time and trouble to install this system on the vehicle. Also, such a system requires a great deal of maintenance to avoid failures, for example.

Stated otherwise, to make the system more easily installable and maintainable, the number of transmission lines should be reduced by getting one transmission line shared by multiple cameras. However, it usually takes a huge channel capacity to transfer the image data of each camera entirely. For that reason, it would be hard for a reduced number of transmission lines to cope with such a tall demand. That is to say, to reduce the number of transmission lines, there is no other choice than cutting down the amount of image data to be transferred.

Also, the image processing section 50 needs to store that huge amount of image data that has been transferred from the cameras 401 on a field-by-field or frame-by-frame basis. Thus, each of the buffer memories 501 should have a great

storage capacity.

Furthermore, although a synthesized image is produced from a plurality of images taken by multiple cameras, not all of each camera image is used for the image synthesis but each  
5 image contains some unnecessary parts. Moreover, even in an image area required for the image synthesis, some part of the area should show a resolution different from that of another during the image synthesis process. Accordingly, it is not always necessary to transmit the entire image data of each  
10 camera image as it is to the image processing section.

#### SUMMARY OF THE INVENTION

An object of this invention is providing a monitoring system that includes multiple cameras and an image processing  
15 section for producing a synthesized image from the images taken by the cameras and that can drastically reduce the amount of image data to be transmitted without sacrificing the quality of the synthesized image.

Specifically, a monitoring system according to the pre-  
20 sent invention includes camera section, transmission path and image processing section. The camera section includes multiple cameras and image data cutdown means. The image data cutdown means reduces the amount of original image data representing camera images captured by the cameras. The camera  
25 section outputs the reduced image data. The transmission path

transmits the reduced image data that has been output from the camera section. The image processing section receives the reduced image data through the transmission path and produces a synthesized image from the reduced image data. The camera  
5 section or the image processing section includes cutdown mode selecting means for selecting a cutdown mode, in which the original image data for use in image synthesis has its amount cut down, for the image data cutdown means in accordance with a correspondence between the synthesized and camera images.

10 According to the present invention, the image data cutdown means, provided for the camera section, reduces the amount of original image data in compliance with the cutdown mode selected by the cutdown mode selecting means. Then, the camera section outputs the reduced image data onto the trans-  
15 mission path. Also, the cutdown mode selecting means selects the cutdown mode, in which the original image data for use in image synthesis has its amount cut down, in accordance with the correspondence between the synthesized and camera images. Accordingly, the image data, which has had its amount cut down  
20 in the cutdown mode selected in accordance with the correspondence between the synthesized and camera images, is transmitted through the transmission path. In this manner, the amount of camera image data to be transmitted can be reduced drastically without sacrificing the quality of the resultant synthe-  
25 sized image. As a result, the transmission path used may have

a reduced channel capacity. So the transmission path is implementable as a smaller number of less expensive transmission lines or even as a wireless path. Thus, the transmission path is much easier to mount on a vehicle or requires maintenance much less often. In addition, a buffer memory needed for the image processing section may have a much reduced storage capacity.

In one embodiment of the present invention, the image processing section may selectively produce any of multiple types of synthesized images and change the types of the synthesized images to be produced. The cutdown mode selecting means may change the cutdown modes according to the type of the synthesized image to be produced by the image processing section.

In another embodiment of the present invention, the cutdown mode selecting means may include a resolution specifier for specifying resolutions that should be necessary for respective areas of each said camera image for use in the image synthesis to produce the synthesized image. In that case, the image data cutdown means preferably compresses the original image data, representing the camera images for use in the image synthesis, according to the resolutions specified by the resolution specifier. In this particular embodiment, the image data cutdown means preferably compresses the original image data by discrete cosine transform.

In such an embodiment, the original image data has its amount reduced greatly by being compressed according to the resolutions that should be necessary for image synthesis, and then image data in the reduced amount is transmitted. Accordingly, the transmission path may have a much smaller channel capacity. In addition, it is also possible to suppress the aliasing distortion, thus improving the quality of the resultant synthesized image.

In an alternative embodiment, the cutdown mode selecting means may include an area specifier for specifying areas that should be necessary to produce the synthesized image for each said camera image for use in the image synthesis. In that case, the image data cutdown means preferably removes an unnecessary part from the original image data that represents each said camera image for use in the image synthesis. The unnecessary part corresponds to the remaining area of the camera image other than the areas specified by the area specifier.

In such an embodiment, the original image data has its amount reduced drastically before the transmission because the unnecessary part of the original image data, corresponding to the excessive area thereof other than the areas necessary for image synthesis, is removed. Accordingly, the transmission path may have a much smaller channel capacity.

In yet another embodiment, the original image data may be read out from each said camera in an externally controllable

order. In that case, the camera section or the image processing section preferably includes a readout controller for controlling the order, in which the original image data representing each said camera image for use in the image synthesis is read out, in compliance with the shutdown mode selected by the shutdown mode selecting means.

Then, the camera images for use in image synthesis will be read out in the order that has been controlled in compliance with the shutdown mode selected. Accordingly, it is possible to prevent too much data from being transmitted through the transmission path within a limited period of time. Rather, the image data can be transmitted dispersively.

In yet another embodiment, the cameras are preferably mounted on a vehicle to capture images of the vehicle's surroundings.

#### BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a block diagram illustrating a configuration for a monitoring system according to a first embodiment of the present invention.

FIG. 2 illustrates an exemplary arrangement of cameras on a vehicle.

FIG. 3 illustrates exemplary positions of virtual viewpoints for synthesized images.

FIGS. 4A and 4B illustrate an exemplary correspondence

between respective camera images and a resultant synthesized image.

FIGS. 5A and 5B schematically illustrate a correspondence between a synthesized image and a camera image.

5 FIGS. 6A and 6B illustrate how the areas of a camera image may be classified according to resolutions.

FIGS. 7A, 7B and 7C illustrate an exemplary method of deriving resolution data.

FIG. 8 is a block diagram illustrating an exemplary internal configuration for a compressor according to the first embodiment.

FIG. 9 illustrates another exemplary arrangement of cameras on a vehicle.

FIG. 10 is block diagram illustrating, as a comparative example, a monitoring system with an image processing section including LPFs.

FIGS. 11A and 11B illustrate another exemplary method of deriving resolution data.

FIG. 12 is a block diagram illustrating a configuration for a monitoring system according to a second embodiment of the present invention.

FIG. 13 is a block diagram illustrating an exemplary internal configuration for camera and compressor according to the second embodiment.

25 FIG. 14 illustrates an exemplary order in which image

signals are read out from respective cameras.

FIG. 15 is a block diagram illustrating a configuration for a monitoring system according to a third embodiment of the present invention.

FIGS. 16A and 16B illustrate an area necessary for image synthesis.

FIGS. 17A and 17B illustrate two methods of specifying an area necessary for image synthesis.

FIG. 18 is a block diagram illustrating an exemplary internal configuration for a selector according to the third embodiment.

FIG. 19 is a block diagram illustrating a configuration for a known monitoring system.

#### DESCRIPTION OF THE PREFERRED EMBODIMENTS

Hereinafter, preferred embodiments of the present invention will be described with reference to the accompanying drawings.

#### EMBODIMENT 1

FIG. 1 is a block diagram illustrating a configuration for a monitoring system according to a first embodiment of the present invention. The monitoring system shown in FIG. 1 is supposed to be mounted on a vehicle and used as an aid for vehicle driving operations (e.g., parking). Specifically,

5 this system combines together images that have been taken by multiple cameras mounted on a vehicle to produce a synthesized image, which looks as if the vehicle were captured by a camera located over the vehicle, for example. Then, the system presents the virtual image to the driver. By looking at the synthesized image presented, the driver can know an exact positional relationship between his or her own vehicle and its surroundings, and can park his or her vehicle much more safely, for example.

10 As shown in FIG. 1, the monitoring system includes camera section 10, transmission line 15, image processing section 20 and display device 30. The camera section 10 includes a number X of cameras 110 (i.e., cameras No. 1 through No. X), each of which is integrated together with a compressor 15 120 and a transmission adapter (Adp) 130. The compressor 120 compresses an image taken by its associated camera 110. The image data, representing the respective images taken by these cameras 110, is output from the camera section 10, transmitted through the transmission line 15 and then input to the 20 image processing section 20. That is to say, the transmission line 15 serves as a transmission path that connects the camera and image processing sections 10 and 20 together. On receiving the image data, the image processing section 20 performs various types of processing (including deformation and integration) on the image data, thereby producing a syn- 25

thesized image and presenting it on the display device 30.

FIG. 2 illustrates an exemplary arrangement of cameras in accordance with this embodiment. In the example illustrated in FIG. 2, six cameras Nos. 1 through 6 are mounted at  
5 respective positions on a vehicle. FIG. 3 illustrates exemplary positions of virtual viewpoints for synthesized images. The image processing section 20 produces a synthesized image, which looks as if the vehicle were seen from the virtual viewpoint No. 1 shown in FIG. 3, for example, from the images taken by the cameras Nos. 1 through 6.  
10

As shown in FIG. 1, the image processing section 20 includes image synthesizer 210, mapping table 220, buffer memory 230, expander 240, transmission adapter (Adp) 250 and resolution specifier 260. The mapping table 220 stores data describing a correspondence between a synthesized image and  
15 respective camera images. The image synthesizer 210 produces a synthesized image by reference to the mapping table 220. The compressed image data is input through the transmission adapter 250 and then decompressed by the expander 240. Then,  
20 the decompressed image data is temporarily retained on the buffer memory 230. In accordance with the correspondence between the synthesized and camera images as described on the mapping table 220, the resolution specifier 260 specifies resolutions, which should be necessary to produce the synthesized image, for respective areas of each camera image. The  
25

resolution specifier 260 is exemplary cutdown mode selecting means as defined in the appended claims.

FIGS. 4A and 4B illustrate an exemplary correspondence between respective camera images and a resultant synthesized image. In the illustrated example, the synthesized image shown in FIG. 4A, which looks as if the vehicle were seen from the virtual viewpoint No. 1 shown in FIG. 3, is produced from the images taken by the cameras Nos. 1 through 6 arranged as shown in FIG. 2. As shown in FIG. 4A, the images taken by the cameras Nos. 1 through 6 will respectively occupy the areas CA1 through CA6 of the synthesized image. In the following description, the areas CA1 through CA6 will be referred to as "camera image areas" CA1 through CA6. In FIG. 4B on the other hand, the camera image areas corresponding to the areas CA1 through CA6 of the synthesized image are identified by CA1' through CA6', respectively.

The mapping table 220 stores data representing the correspondence between the synthesized and respective camera images such as that shown in FIG. 4A. That is to say, the data stored on the mapping table 220 describes camera image data associated with every set of coordinates included in the synthesized image that should look as such to the virtual viewpoint. By reference to the data stored on the mapping table 220, the image synthesizer 210 produces the synthesized image that looks as if the vehicle were seen from the virtual view-

point.

For example, a point **P1** on the synthesized image is located in an area **OA** in which the image areas **CA1** and **CA6** of the cameras Nos. 1 and 6 overlap with each other. Accordingly, pixel data is obtained for this point **P1** using pixel data associated with the point **P1** in the area **CA1'** of the camera No. 1 image and pixel data associated with the point **P1** in the area **CA6'** of the camera No. 6 image. On the other hand, a point **P2** on the synthesized image is located in the image area **CA1** of the camera No. 1. Accordingly, pixel data is obtained for the point **P2** using pixel data associated with the point **P2** in the area **CA1'** of the camera No. 1 image.

Also, in accordance with the correspondence between the synthesized and respective camera images as described on the mapping table **220**, the resolution specifier **260** specifies resolutions that should be necessary for image synthesis for the respective areas of each camera image. The data, representing the resolutions specified for each camera image, is transmitted through the transmission adapter **250** and transmission line **15** to a compressor **120** associated with the camera image. In accordance with the resolution data transmitted, the compressor **120** compresses the image data of the associated camera image. The compressed image data is transmitted through the transmission adapter **130** and transmission line **15** to the image processing section **20**. In the image processing section **20**,

the compressed image data is decompressed by the expander 240 and then the decompressed image data is stored on the buffer memory 230.

Also, the mapping table 220 stores multiple sets of mapping table data that are associated with a plurality of virtual viewpoints as shown in FIG. 3. In response to a selection signal externally input, the mapping table 220 can select one of those sets of mapping table data for use in the image synthesis. In this manner, the image processing section 20 can selectively produce one of multiple types of synthesized images and can change the types of the synthesized images to be produced. The selection signal may be applied according to the gear position or the speed of a running vehicle, for example.

When the selection signal is input, the previous set of mapping table data that has been output by the mapping table 220 is replaced with another. As a result, a different type of synthesized image is produced. On receiving the newly selected set of mapping table data, the resolution specifier 260 specifies again the resolutions that should be necessary for image synthesis for respective areas of each camera image. The resolution data newly obtained is transmitted through the transmission line 15 to the compressor 120 associated with each camera image. And in accordance with the resolution data transmitted, the compressor 120 changes the modes of compres-

sion processing to be carried out.

### *Compression processing*

In the illustrated embodiment, each of the compressors  
5 120 is supposed to compress the associated camera image data  
by discrete cosine transform (DCT).

For example, first, the compressor 120 divides its asso-  
ciated camera image made up of  $480 \times 720$  pixels into 5400 mac-  
roblocks, each consisting of  $8 \times 8$  pixels. As a result of this  
10 division, camera image data with coordinates  $(i, j)$  (where  $1 \leq i \leq 480$ ,  $1 \leq j \leq 720$ ) may be represented as  $S1(K, L, i', j')$ ,  
where  $K$  and  $L$  respectively are horizontal and vertical block  
address numbers, i.e.,  $1 \leq K \leq 60$ ,  $1 \leq L \leq 90$ ,  $1 \leq i' \leq 8$  and  $1 \leq j' \leq 8$ .

15 Then, each pixel data  $S1(K, L, i', j')$  is transformed  
into a signal  $g1(K, L, m, n)$  with respective frequency compo-  
nents by the DCT transform given by

$$g1(K, L, m, n) = \frac{2}{N} C(m) C(n) \sum_{i'=1}^N \sum_{j'=1}^N S1(K, L, i', j') \cdot \cos\left[\frac{\pi K(2i'-1)}{2N}\right] \cdot \cos\left[\frac{\pi L(2j'-1)}{2N}\right]$$

(N=8, m=1~8, n=1~8)

20 In this equation, a great  $m$  or  $n$  value represents a high hori-  
zontal or vertical frequency component in a macroblock. If  
the data representing those high-frequency components are re-  
moved, data with a low resolution can be generated easily and  
25 the camera image can be transmitted in a reduced amount. In

some type of synthesized image, a horizontal resolution required may be different from a vertical resolution required. Even so, if the m and n values as thresholds for removing the excessive data are set independently, it is possible to separately control the resolutions both horizontally and vertically.

FIGS. 5A and 5B schematically illustrate a correspondence between a synthesized image and a camera No. 1 image. Specifically, FIG. 5A illustrates a map for the camera No. 1 image on the synthesized image, while FIG. 5B illustrates a map for the synthesized image on the camera No. 1 image. As shown in FIGS. 5A and 5B, the open circles A and B on the synthesized image are associated with the circles A' and B' on the camera No. 1 image. As used herein, the "map" means a lattice, which is drawn for convenience sake to clarify the correspondence between the synthesized and camera images. The lattice is drawn at regular pixel intervals in dashed lines for the synthesized image shown in FIG. 5A and in solid lines for the camera No. 1 image shown in FIG. 5B. The solid-line lattice on the camera No. 1 image also represents "blocks" as units for subsequent DCT compression. In the synthesized image shown in FIG. 5A, part of the camera No. 1 image map with a relatively high lattice density (e.g., the circle A) does not require so high a resolution for the camera No. 1 image data. On the other hand, part of the camera No. 1 image map

with a relatively low lattice density (e.g., the circle **B**) does require a high resolution for the camera No. 1 image data. That is to say, in the camera No. 1 image shown in FIG. 5B, part of the synthesized image map with a relatively high lattice density (e.g., the circle **B'** associated with the circle **B**) does require a high resolution for the camera No. 1 image data. However, part of the synthesized image map with a relatively low lattice density (e.g., the circle **A'** associated with the circle **A**) does not require so high a resolution for the camera No. 1 image data. Also, the image data, not included in the lattice representing the synthesized image map, is not necessary for the image synthesis.

That is to say, the camera No. 1 image data may be classified into three types of blocks **BL1**, **BL2** and **BL3** as shown in FIGS. 6A and 6B. Specifically, the block **BL1** is not necessary for the image synthesis, the block **BL2** requires high-resolution image data and the block **BL3** needs only low-resolution image data.

By reference to the data stored on the mapping table 220, the resolution specifier 260 derives resolutions data  $R_{xv}(K, L)$  and  $R_{xh}(K, L)$  for each macroblock, where  $x$  is the camera number (i.e.,  $1 \leq x \leq X$ ) and  $h$  and  $v$  are horizontal and vertical directions, respectively. Hereinafter, it will be described in detail with reference to FIG. 7 how to derive the resolution data  $R_{xv}(K, L)$  and  $R_{xh}(K, L)$ .

First, by reference to the data stored on the mapping table 220, it is determined whether or not any point in a macroblock of each camera image has its associated coordinates on the synthesized image. The block BL1, including no points associated with any sets of coordinates on the synthesized image, is not necessary for the image synthesis. Accordingly, the resolution data Rxv (K, L) and Rxh (K, L) for every point in the block BL1 should be zero.

If any point (i', j') associated with coordinates (i, j) on the synthesized image shown in FIG. 7A exists on a macroblock of the camera image, then three more points, respectively associated with the coordinates (i+1, j), (i+1, j+1) and (i, j+1) on the synthesized image, are obtained for the macroblock. Then, an area IM1, surrounded by the point (i', j') and the three other points, is defined as shown in FIG. 7B. Next, using the vertical and horizontal sizes Lv and Lh (which are integers) of the area IM1 shown in FIG. 7C, the resolution data Rxv (K, L) and Rxh (K, L) is derived by the following equations:

$$Rxv (K, L) = 8/Lv$$

$$Rxh (K, L) = 8/Lh$$

where the remainder should be rounded up. The resolution specifier 260 transmits the resolution data Rlv (K, L) through RXv (K, L) and Rlh (K, L) through RXh (K, L) obtained this way to the compressors 120 for the respective cameras 110 through

the transmission line 15.

Strictly speaking, the area of the camera image occupied by the four pixels associated with the coordinates  $(i, j)$  on the synthesized image is not equal to the area **IM** but actually an area surrounded by the four points associated with the coordinates  $(i-0.5, j-0.5)$ ,  $(i-0.5, j+0.5)$ ,  $(i+0.5, j-0.5)$  and  $(i+0.5, j+0.5)$ , respectively, on the synthesized image. However, the latter area has almost the same shape as the area **IM1** and the points associated with the coordinates  $(i, j)$ ,  $(i+1, j)$ ,  $(i+1, j+1)$  and  $(i, j+1)$  on the synthesized image can be easily obtained by reference to the mapping table 220. For that reason, the resolution data  $R_{xv}(K, L)$  and  $R_{xh}(K, L)$  is herein derived based on the size of the area **IM**.

In accordance with the resolution data  $R_{xv}(K, L)$  and  $R_{xh}(K, L)$  transmitted, each compressor 120 removes unnecessary components from the signal  $g_x(K, L, m, n)$  with respective frequencies for each macroblock of the associated camera image. Then, the compressor 120 transmits only the necessary components to the image processing section 20. Specifically, the compressor 120 removes components with  $m$  values greater than  $R_{xv}(K, L)$  and  $n$  values greater than  $R_{xh}(K, L)$ . In this case, the resolution data  $R_{xv}(K, L)$  and  $R_{xh}(K, L)$  of each and every point in the block **BL1** is zero. Accordingly, all the components in the block **BL1** are removed.

FIG. 8 illustrates an exemplary internal configuration

for the compressor 120 associated with the camera No. 1. The compressor 120 includes three 8-line memories 121a, 121b and 121c and can store image signals corresponding to 24 ( $=8 \times 3$ ) lines in total.

5        When the resolution data  $Rlv(K, L)$  through  $RXv(K, L)$  and  $Rlh(K, L)$  through  $RXh(K, L)$  arrives by way of the transmission line 15, each transmission adapter 130 selectively receives the resolution data for the associated camera. In the illustrated example, the transmission adapter 130 receives the  
10 resolution data  $Rlv(K, L)$  and  $Rlh(K, L)$  associated with the camera No. 1. Then, the transmission adapter 130 stores the resolution data on a resolution data memory 124.

On the other hand, the camera 110 is sending out image signals as time-series data along the scan lines just like TV  
15 signals. Accordingly, a time  $t$ , at which a signal associated with a set of coordinates  $(i, j)$  on the screen are input, is given by

$$t = T_{pix} \cdot (i \cdot (720 + B_h) + j)$$

where  $T_{pix}$  is a time per pixel and  $B_h$  is the number of horizontal  
20 blanking pixels.

The image signals, sent out from the camera 110, are sequentially stored on the respective 8-line memories 121a, 121b and 121c. In this case, part of the image signal associated with an  $i^{th}$  line is stored at a  $\text{mod}(i, 24)^{th}$  line. As  
25 used herein,  $\text{mod}(K, L)$  means the remainder obtained by divid-

ing K by L.

When the first image signal has been stored to the eighth line on the first 8-line memory 121a, the next image signal for the ninth and succeeding lines starts to be stored on the second 8-line memory 121b. On the other hand, a digital signal processor (DSP) 122 reads out the image signal, corresponding to the number  $8 \times 720$  of pixels, as a signal  $S1$  ( $1, L, i', j'$ ) (where  $1 \leq L \leq 90$ ,  $1 \leq i' \leq 8$  and  $1 \leq j' \leq 8$ ) for ninety  $8 \times 8$  pixel macroblocks from the first 8-line memory 121a. Then, the DSP 122 performs the DCT transform on each of these macroblocks, thereby calculating  $g1$  ( $1, L, m, n$ ). Furthermore, by using the resolution data  $Rlv$  ( $1, L$ ) and  $Rlh$  ( $1, L$ ) stored on the resolution data memory 124, the DSP 122 removes all components with  $m$  values greater than  $Rlv$  ( $1, L$ ) and with  $n$  values greater than  $Rlh$  ( $1, L$ ) from  $g1$  ( $1, L, m, n$ ).

Accordingly, at this point in time, the image signal  $S1$  ( $i, j$ ) (where  $1 \leq i \leq 8$  and  $1 \leq j \leq 720$ ) stored on the first 8-line memory 121a is the following data sequence:

$g1$  ( $K=1, 1 \leq L \leq 90$ )

( $L=1$ ):  $d1, d2, \dots, dmn$

( $L=2$ ):  $d1, d2, \dots, dmn'$

.....

( $L=90$ ):  $d1, d2, \dots, dmn''$

where  $mn = Rlv(1, 1) \cdot Rlh(1, 1)$ ,  $mn' = Rlv(1, 2) \cdot Rlh(1,$

2) and  $mn'' = Rlv(1, 90) \cdot Rlh(1, 90)$ . As can be seen, the respective macroblocks include mutually different numbers of data items. That is to say, the image signal stored on the first 8-line memory 121a is transformed into a data sequence  
 5 in which each macroblock includes a number  $(Rlv(1, L) \cdot Rlh(1, L))$  of data items. This data sequence is once stored on a DCT data buffer memory 123 and then transmitted by the transmission adapter 130 to the image processing section 20 by way of the transmission line 15.

10 On receiving this data sequence, the expander 240 performs inverse DCT (IDCT) transform on the data sequence, thereby restoring the image signal as  $S1'(1, L, i', j')$ . Then, the expander 240 stores the restored image signal on the buffer memory 230. The restored image signal  $S1'(1, L,$   
 15  $i', j')$  has already had its high-frequency components removed during the DCT transform and is equivalent to a signal obtained by subjecting the original signal  $S1(1, L, i', j')$  to low pass filtering (LPF) processing.

Next, when the second image signal has been stored to  
 20 the sixteenth line on the second 8-line memory 121b, the next image signal for the seventeenth and succeeding lines starts to be stored on the third 8-line memory 121c. On the other hand, the DSP 122 reads out the image signal, corresponding to the number  $8 \times 720$  of pixels, as a signal  $S1(2, L, i', j')$   
 25 (where  $1 \leq L \leq 90$ ,  $1 \leq i' \leq 8$  and  $1 \leq j' \leq 8$ ) for ninety  $8 \times 8$  pixel

macroblocks from the second 8-line memory 121b. Then, the DSP 122 performs the DCT transform on each of these macroblocks, thereby deriving  $g1(2, L, m, n)$ . Furthermore, by using the resolution data  $Rlv(2, L)$  and  $Rlh(2, L)$  stored on the resolution data memory 124, the DSP 122 removes all components with  $m$  values greater than  $Rlv(2, L)$  and with  $n$  values greater than  $Rlh(2, L)$  from  $g1(2, L, m, n)$ .

Accordingly, at this point in time, the image signal stored on the second 8-line memory 121b is the following data sequence:

$g1(K=2, 1 \leq L \leq 90)$

$(L=1): d1, d2, \dots, dmn$

$(L=2): d1, d2, \dots, dmn'$

.....

$(L=90): d1, d2, \dots, dmn''$

where  $mn = Rlv(2, 1) \cdot Rlh(2, 1)$ ,  $mn' = Rlv(2, 2) \cdot Rlh(2, 2)$  and  $mn'' = Rlv(2, 90) \cdot Rlh(2, 90)$ . As can be seen, the respective macroblocks include mutually different numbers of data items. That is to say, the image signal stored on the second 8-line memory 121b is transformed into a data sequence in which each macroblock includes a number  $(Rlv(2, L) \cdot Rlh(2, L))$  of data items. In the same way, this data sequence is also transmitted through the transmission line 15 to the image processing section 20 and then restored by the expander 240 into an image signal  $S1'(2, L, i', j')$ .

The same operation will be repeatedly performed until  $K=60$ . In this manner, image signals  $S1' (K, L, i', j')$  corresponding to one frame are restored and then stored on the buffer memory 230.

Also, the compressor 120 associated with each of the other cameras 110 also transmits compressed image data to the expander 240, which also restores image signals  $Sx' (K, L, i', j')$  (where  $2 \leq x \leq X$ ) and then stores them on the buffer memory 230. Then, the image synthesizer 210 produces a synthesized image from the respective camera image data stored on the buffer memory 230 by the known method.

As described above, the camera section 10 of this embodiment compresses the image data of each camera image and then transmits just a part of the image data with specified resolutions in accordance with the correspondence between the synthesized and respective camera images as described on the mapping table 220. Accordingly, the transmission line 15 may have a smaller channel capacity. As a result, the monitoring system ensures more stabilized data transmission and can use an even less expensive transmission line.

That is to say, the transmission lines for the respective cameras can be easily integrated into just one transmission line 15 as shown in FIG. 2. Thus, the transmission line 15 is much easier to mount on a vehicle and needs maintenance much less often. Alternatively, as shown in FIG. 9, the transmis-

stored on one of the 8-line memories 121a, 121b and 121c, the compressor 120 starts to perform the DCT transform and transmission. Accordingly, the compression and transmission causes a minimum signal propagation delay.

5 In addition, the operation of compressing each camera image may also have its modes changed depending on the type of the synthesized image to be produced by the image processing section 20. In that case, every time the mapping tables for use in image synthesis are changed, the resolution specifier  
10 260 should newly obtain the resolution data  $R_{xv}(K, L)$  and  $R_{xh}(K, L)$  and then transmit it to the compressors 120 for the respective cameras 110 through the transmission line 15.

Alternatively, resolution data sets corresponding to the respective mapping tables may also be stored beforehand on a  
15 ROM, for example, provided for the resolution specifier 260. In that case, the selection signal should also be input to the resolution specifier 260 so that the resolution specifier 260 can change the resolution data sets when the mapping tables are changed in response to the selection signal. Then, there  
20 is no need to perform the process step of newly obtaining the resolution data every time the mapping tables are changed.

As another alternative, the compressor 120 may also include a memory for pre-storing the resolution data sets, corresponding to the respective mapping tables, thereon. Then,  
25 every time the mapping tables are changed, the image process-

ing section 20 has only to send the ID of the mapping table newly selected to the compressors 120. Alternatively, instead of getting the mapping table ID sent from the image processing section 20, the selection signal may also be input to the re-  
5 spective compressors 120 in the camera section 10 so that the compressors 120 can change the resolution data sets every time the mapping tables are changed.

In the foregoing embodiment, a DCT transform is supposed to be carried out to compress the image data. Optionally, the  
10 DCT transformed data may be further subjected to quantization in compliance with the JPEG, for example. Also, similar effects are attainable by a wavelet or Fourier transform, not just by the DCT transform.

#### 15 *Elimination of aliasing distortion*

In addition, according to this embodiment, it is possible to easily avoid an undesirable situation where the synthesized image has its quality lowered by aliasing distortion.

In the example shown in FIGS. 7A and 7B, the area IM1 on  
20 the camera image, corresponding to the coordinates (i, j) on the synthesized image, has a size greater than that of one pixel of the camera image. That is to say, the area IM1 contains a number of pixels. To obtain an optically accurate synthesized image, a weighted average of the data represented  
25 by those pixels contained in the area IM1 should be obtained

as the pixel data corresponding to the coordinates (i, j). Specifically, the pixel data S (i, j) of the synthesized image should be given by

$$S(i, j) = \sum \gamma_p \cdot (S1(i_p, j_p))$$

5 where S1 (i<sub>p</sub>, j<sub>p</sub>) is the camera pixel data, p is the number of camera pixel and  $\gamma_p$  is a coefficient that has been determined considering the percentage of the pixel included in the area IM1. In that case, however, to obtain a signal corresponding to one pixel of the synthesized image, 10 the computation should be carried out with signals corresponding to multiple pixels read out from the buffer memory 230. This method is far from being practical because the image synthesizer 210 must perform a huge amount of computation.

15 For that reason, a so-called "nearest" approximation method has been used in the art. According to the nearest method, only a signal corresponding to just one pixel located nearest to the center of the area IM1 is used as the signal corresponding to the coordinates (i, j).

20 The nearest method, however, often results in aliasing distortion, which is typically observed when a signal that was sampled at a high rate is sub-sampled at a low sampling rate without cutting off the high-frequency components thereof. That is to say, if simplified image synthesis is carried out 25 by the nearest method using a high-resolution image signal as

it is, then the aliasing distortion might arise in part of the image that may have a low resolution, thus possibly lowering the quality of the synthesized image.

To eliminate the aliasing distortion, those unwanted  
5 high-frequency components could be cut off in advance by getting the image signal of each camera pre-processed by its associated low-pass filter (LPF) 51 as shown in FIG. 10.

In that case, however, each LPF 51 should have its frequency characteristics controlled adaptively to every part of  
10 the associated camera image, because a resolution necessary for a part of the camera image might be different from one required for another part thereof. That is to say, the LPF 51 should have a rather complicated circuit configuration. On  
the other hand, if an LPF exhibiting constant frequency characteristics is used, then the LPF may have a simple circuit  
15 configuration. But the LPF automatically cuts off the high-frequency components from even a part requiring a high resolution. Accordingly, the resultant synthesized image cannot have the required resolutions fully.

In contrast, according to this embodiment, the aliasing distortion much less likely arises in the low-resolution image portion, although the aliasing distortion often occurs there normally. This is because the compressor 120 has already removed those high-frequency components from that image portion  
25 according to the size of the area IM1. That is to say, the

camera image signal, restored by the expander 240, is equivalent to a version of the original signal that has been subjected to the LPF processing adaptively depending on the resolutions required. Thus, the monitoring system of this embodiment can suppress the aliasing distortion sufficiently and can improve the quality of the resultant synthesized image significantly without using those overly complicated LPFs.

In the foregoing example, the present invention is applied to the nearest method. Alternatively, the present invention is equally applicable to any other method. For example, this invention is obviously applicable to a bilinear method in which linear interpolation is carried out using signals associated with four pixels that surround the center of the area IM1 corresponding to the coordinates (i, j).

#### *Alternative compression method*

In the foregoing embodiment, the resolution specifier 260 obtains the resolution data Rxv (K, L) and Rxh (K, L) using the horizontal and vertical sizes Lh and Lv of the area IM1 shown in FIG. 7C. Alternatively, the resolution data may also be obtained by a different method.

Like FIG. 7B, FIG. 11A also illustrates the area IM1 occupied by one pixel of the synthesized image on the camera image. In this alternative method, the area IM1 is placed at the center of an 8×8 macroblock as shown in FIG. 11B and a

coefficient  $\gamma_p$  is obtained for each pixel while considering the percentage of the pixel included in the area IM1. When a weighted average of multiple pixels included in a camera image is used to produce an optically accurate synthesized image, this coefficient  $\gamma_p$  is used to weight each of those pixels.

Specifically, a coefficient  $r(i', j')$  is expanded into a coefficient for the  $8 \times 8$  macroblock while supposing the center of the area IM1 to be represented by  $(i', j') = (1, 1)$ . Then, as in an image signal, the coefficient is subjected to a DCT transform, thereby obtaining a transform coefficient  $h(K, L, m, n)$ . This transform coefficient  $h(K, L, m, n)$  is a DCT transform coefficient representing the LPF characteristics shown by the coefficient  $\gamma_p$  and has smaller high-frequency components.

Thus, the upper limits of the  $m$  and  $n$  values in the transform coefficient  $h(K, L, m, n)$  with a predetermined threshold value or more are defined as the values of the resolution data  $R_{xv}(K, L)$  and  $R_{xh}(K, L)$ . The resolution specifier 260 transmits not only the resolution data  $R_{xv}(K, L)$  and  $R_{xh}(K, L)$  but also the transform coefficient  $h(K, L, m, n)$  with the predetermined threshold value or more to the compressor 120.

In response, the compressor 120 removes the high-frequency components from the DCT transformed data  $g_x(K, L,$

m, n) of the image signal using the resolution data Rxv (K, L) and Rxh (K, L). Next, the compressor 120 multiplies the remaining DCT transformed data gx (K, L, m, n) by a transform coefficient hx (K, L, m, n) and then sends the product to the  
5 expander 240.

In accordance with this method, a signal restored by the expander 240 through IDCT transform is approximately equal to a version of the original signal that has been subjected to LPF processing using the coefficient  $\gamma_p$ . Thus, compared to  
10 the first embodiment, a more optically accurate synthesized image can be produced.

It should be noted that the resolution data Rxv (K, L) and Rxh (K, L) is also definable without using the area IM1. For example, a block unnecessary for image synthesis may have  
15 resolution data Rxv (K, L) and Rxh (K, L) of zero, while a block necessary for image synthesis may have resolution data Rxv (K, L) and Rxh (K, L) of a fixed non-zero value.

## EMBODIMENT 2

FIG. 12 is a block diagram illustrating a configuration for a monitoring system according to a second embodiment of the present invention. The monitoring system shown in FIG. 12 is basically the same as the counterpart shown in FIG. 1. In FIG. 12, each component also shown in FIG. 1 is identified  
25 by the same reference numeral and the detailed description

thereof will be omitted herein.

The system shown in FIG. 12 is different from the counterpart shown in FIG. 1 in that the image processing section 20A of the system shown in FIG. 12 further includes readout controller 270 and sync signal generator 280. In response to the output of the resolution specifier 260, the readout controller 270 generates a readout control signal for each camera 110A. The sync signal generator 280 generates a sync signal for each camera 110A. The readout control and sync signals, output from the readout controller 270 and sync signal generator 280, respectively, are transmitted from the transmission adapter 250 to the camera sections 10A by way of the transmission line 15. The readout control and sync signals transmitted will be sent to the compressors 120A and cameras 110A by way of the respective transmission adapters 130.

Synchronously with the rise of the sync signal transmitted, each camera 110A captures a frame picture. In the illustrated embodiment, each camera 110A is supposed to capture image data consisting of  $720 \times 480$  pixels every  $1/60$  second.

FIG. 13 is a block diagram illustrating an exemplary internal configuration for the camera 110A and compressor 120A. As shown in FIG. 13, the camera 110A includes: imager (e.g., CCD in this embodiment) 111; optical system 112 with a lens; readout/synchronization controller 113; and ADC/processor 114. The ADC/processor 114 performs an analog-to-digital conversion

on the output of the imager 111 and then various types of signal processing (including color separation) on the resultant digital signal.

The imager 111 includes imaging plane and storage each  
5 corresponding to one frame picture. First, incoming light is incident through the optical system 112 onto the imaging plane of the imager 111 and sensed as a light intensity signal thereon. Then, a phototransistor associated with each pixel converts the light intensity signal into an electrical charge  
10 signal. The electrical charge signal will be stored for one frame interval (e.g., 1/60 second in this embodiment) and then transferred as an image signal to the storage.

In a normal CCD, the image signal, which has been accumulated on the storage, is sequentially read out along the  
15 scan lines. Typically, the upper left corner of one frame picture is read out first. In the meantime, another light intensity signal, which has just been sensed by the imaging plane, is converted into another electrical charge signal, which is then stored as an image signal for the next frame.

20 In contrast, according to this embodiment, the imager 111 can read the image signal either from the upper left or lower left corner of one frame picture. And the order of reading the image signal is controlled by the readout/synchronization controller 113.

25 In the second embodiment, the image processing section

20A controls the order, in which the image data obtained by each of the cameras 110A is read out, in accordance with the correspondence between the synthesized and respective camera images.

5        FIG. 14 illustrates an exemplary order in which the image signal is read out from each of the cameras 110A. In FIG. 14, the areas CA1' through CA6' of the respective camera images are the same as the counterparts shown in FIG. 4B and are all necessary for image synthesis. As shown in FIG. 14, 10 the lower part of each camera image is an area necessary for the image synthesis, while the upper part thereof is unnecessary for the image synthesis.

In the illustrated embodiment, the readout controller 270 generates a readout control signal instructing that the 15 image signal captured by the camera No. 1, 3 or 5 should be read out from the upper left corner of one frame picture and that the image signal captured by the camera No. 2, 4 or 6 should be read out from the lower left corner thereof as indicated by the arrows in FIG. 14. In response to the readout control signal 125 transmitted, the readout/synchronization 20 controller 113 for each camera 110A controls the imager 111 as shown in FIG. 13. The output of the imager 111 is A-D converted and then subjected to various types of signal processing like color separation by the ADC/processor 114. Then, the 25 digital signal processed is sequentially sent as image signals

to the 8-line memories 121 in the compressor 120A.

As for the image signal captured by the camera No. 1, 3 or 5, a signal corresponding to coordinates (i, j) on a synthesized image is sent at the time t given by

5 
$$t = T_{pix} \cdot (i \cdot (720 + B_h) + j)$$

as in the first embodiment. On the other hand, the image signal captured by the camera No. 2, 4 or 6 is scanned from the lower left corner of one frame picture. Accordingly, unlike the first embodiment, a signal corresponding to coordinates (i, j) on a synthesized image is sent at the time t given by

$$t = T_{pix} \cdot ((480 - i) \cdot (720 + B_h) + j)$$

where  $T_{pix}$  is a time per pixel and  $B_h$  is the number of horizontal blanking pixels.

15 Accordingly, as in the first embodiment, the first image signal captured by the camera No. 1 is converted into the following data sequence in which the respective macroblocks have mutually different numbers of data items:

$$g1 \ (K=1, 1 \leq L \leq 90)$$

20 
$$(L=1): d1, d2, \dots, d_{mn}$$

$$(L=2): d1, d2, \dots, d_{mn'}$$

.....

$$(L=90): d1, d2, \dots, d_{mn''}$$

where  $mn = R1v(1, 1) \cdot R1h(1, 1)$ ,  $mn' = R1v(1, 2) \cdot R1h(1,$

25  $2)$  and  $mn'' = R1v(1, 90) \cdot R1h(1, 90)$ . In contrast, the

first image signal captured by the camera No. 2 is converted into the following data sequence in which the respective macroblocks have mutually different numbers of data items:

5           g2 (K=60,  $1 \leq L \leq 90$ )

          (L=1): d1, d2, ..., dmn

          (L=2): d1, d2, ..., dmn'

          .....

          (L=90): d1, d2, ..., dmn''

10       where  $mn = R2v(60, 1) \cdot R2h(60, 1)$ ,  $mn' = R2v(60, 2) \cdot R2h(60, 2)$  and  $mn'' = R2v(60, 90) \cdot R2h(60, 90)$ .

Next, it will be described how much data should be transmitted through the transmission line 15 when compressed image signals are sent out from the respective cameras 110A.

15       As for the first image signal sent out from the camera No. 1, 3 or 5 for the first eight lines of one frame picture, mn through mn'' are almost zero, i.e., only data with almost zero quantity is transmitted therefrom. On the other hand, the first image signal transmitted from the camera No. 2, 4  
20       or 6 for the first eight lines of one frame picture has a considerable amount of data necessary for image synthesis. As for the last image signal sent out from the camera No. 2, 4 or 6 for the last eight lines of one frame picture, mn through mn'' are almost zero, i.e., only data with almost zero  
25       quantity is transmitted therefrom. On the other hand, the

last image signal transmitted from the camera No. 1, 3 or 5 for the last eight lines of one frame picture has a considerable amount of data necessary for image synthesis.

As can be seen, if the image signal is read out from the camera No. 1, 3 or 5 in the order opposite to that of the camera No. 2, 4 or 6, then the amount of data transmitted through the transmission line 15 can be dispersed with time. Accordingly, the transmission line 15 may have a relatively small channel capacity.

Even for the first embodiment, the amount of data transmitted through the transmission line 15 can also be dispersed with time. For example, the DCT data buffer memory 123 in the compressor 120 may have so large a capacity that the data transmission is controllable on the transmitting end of the DCT data buffer memory 123. Then, the amount of data transmitted can be dispersed with time.

In that case, however, a huge amount of data should be stored on the DCT data buffer memory 123 albeit temporarily. Thus, the data transmitted from the camera 110 to the image processing section 20 is delayed for a longer time. Generally speaking, the driver, or the user of this monitoring system, drives his or her vehicle while looking at the synthesized image on the screen. Accordingly, considering the response speed at outputting the synthesized image, such a delay should preferably be as short as possible. Thus, the

second embodiment is more advantageous than the first embodiment in this respect.

As described above, according to the second embodiment, an image signal captured by each camera is read out in the order that has been controlled in accordance with the correspondence between the synthesized and camera images. Thus, the amount of data transmitted can be dispersed with time without decreasing the response speed at outputting the synthesized image.

It should be noted that the image signal readout orders shown in FIG. 14 are just illustrative ones. Accordingly, the readout control may also be performed so that the image signal is read out from the upper left corner of a picture taken by the camera No. 1, 2 or 3 and from the lower left corner of a picture taken by the camera No. 4, 5 or 6, for example. Furthermore, if the correspondence between the synthesized and camera images has changed, then the image signal readout order may also be changed. In the foregoing embodiment, the imager 111 is so constructed as to provide two types of readout orders. Alternatively, the imager 111 may also realize three or more types of readout orders. Then, an appropriate one of the readout orders should be selected depending on the correspondence between the synthesized and camera images.

In the foregoing embodiment, a CCD is supposed to be

used as the imager. Alternatively, a CMOS device may also be used as the imager. A camera including a CCD outputs an image signal corresponding to the entire frame along the scan lines. On the other hand, a camera including a CMOS device  
5 can selectively output an image signal corresponding to just a part of one frame (e.g., a rectangular area). Accordingly, if a camera including a CMOS device is used, the image signal captured by each camera can be read out in a more finely controlled order. As a result, the amount of data transmitted  
10 can be dispersed with time more efficiently.

### EMBODIMENT 3

FIG. 15 is a block diagram illustrating a configuration for a monitoring system according to a third embodiment of the present invention. The monitoring system shown in FIG.  
15 15 has basically the same configuration as the counterpart of the first embodiment shown in FIG. 1.

The third embodiment of the present invention is different from the first embodiment in that the system of the third  
20 embodiment cuts down the amount of each camera image by removing the image data of an area that should be unnecessary for image synthesis, not by compressing the image data. For that purpose, the image processing section 20B of the third embodiment includes an area specifier 290 as alternative cut-  
25 down mode selecting means instead of the resolution specifier

260. The area specifier 290 specifies the area that should be necessary for image synthesis for each camera image. Also, the camera section 10B of the third embodiment does not include the compressors 120 but selectors 140. Each of the selectors 140 removes the image data from the entire area of the associated camera image but the area specified by the area specifier 290. Furthermore, since this system performs no image compression, the image processing section 20B does not include the expander 240.

In accordance with the correspondence between the synthesized and camera images as described on the mapping table 220, the area specifier 290 specifies the area that should be necessary for image synthesis for each camera image. The information representing the areas specified is transmitted from the transmission adapter 250 to the respective selectors 140 in the camera section 10B by way of the transmission line 15.

In response to the area information provided, each selector 140 selectively outputs the data about only the necessary area of the associated camera image. The image data output is transmitted from the associated transmission adapter 130 to the image processing section 20B by way of the transmission line 15. In the image processing section 20B, the image data transmitted is stored on the buffer memory 230 first. Then, by reference to the data stored on the mapping table 220, the image synthesizer 210 produces a synthesized

image from the image data stored on the buffer memory 230.

FIGS. 16A and 16B schematically illustrate a relationship between the image taken by the camera No. 1 and an area ANE necessary for image synthesis. As shown in FIG. 16B, the

5 area ANE necessary for image synthesis can be obtained from the location of the synthesized image map on the camera No. 1 image shown in FIG. 16A. For example, the area specifier 290 obtains a rectangular area AN1 including the necessary area ANE as shown in FIG. 17A, and then outputs the coordinates

10 (Is, Js) and (Ie, Je) at the upper left and lower right corners of the rectangular area AN1 as information representing the area AN1. In the same way, the area specifier 290 also defines a similar rectangular area, which should be necessary in producing a synthesized image, for each of the other camera  
15 images and then outputs the coordinates at the upper left and lower right corners of the rectangular area obtained.

FIG. 18 is a block diagram illustrating an exemplary internal configuration for the selector 140. Hereinafter, it will be described with reference to FIG. 18 how the selector  
20 140 operates.

The image signals output from the camera 110 are sequentially written onto three line memories 141a, 141b and 141c. On the other hand, area data, representing the areas specified for the respective camera images, has been transmitted through  
25 the transmission line 15 to the transmission adapters 130.

Each of the adapters 130 selectively takes only a part of the area data for the associated camera 110 and then gets the area data stored on an area data memory 144.

When a predetermined amount of image data has been written on one of the line memories 141a, 141b or 141c, a DSP 142 reads out the image data from the line memory 141a, 141b or 141c. Next, the DSP 142 selects only a part of the image data that should be included in a rectangular area as defined by the area data stored on the area data memory 144, and then gets the selected image data stored on a data buffer memory 143. The image data stored on the data buffer memory 143 is additionally provided with camera number, line numbers and headers representing the numbers of data items as follows:

(Camera No. 1)(Line No. 1)(No. of Data M1): d1, ..., dM1

(Camera No. 1)(Line No. 2)(No. of Data M2): d1, ..., dM2

.....

(Camera No. 1)(Line No. 480)(No. of Data M480): d1, ..., dM480

Then, the image data with these identifiers is transmitted from the transmission adapter 130 to the image processing section 20B by way of the transmission line 15.

The number  $M_i$  of data items for a line No.  $i$  is given by

$M_i = J_e - J_s + 1$  if  $I_s \leq i \leq I_e$

$M_i = 0$  otherwise

That is to say, the amount of image data to be transmitted through the transmission line can be cut down considerably

compared to a known method that supposes that the image data should be all transmitted.

In the foregoing embodiment, the area specifier 290 defines a rectangular area **AN1** including an area **ANE** necessary for image synthesis and then transmits coordinate information, representing the rectangular area **AN1**, to the respective selectors 140. However, the present invention is not limited to such a specific embodiment. For example, as shown in FIG. 17B, each camera image may be digitized with the area **ANE** necessary for image synthesis represented as "1" and the unnecessary area **AUN** represented as "0". In that case, run length data, obtained by scanning the camera image along horizontal scan lines, may be transmitted. Then, in accordance with the run length data transmitted, each selector 140 selectively transmits only a part of its associated camera image data, corresponding to the area **ANE**, to the image processing section 20B.

Also, as in the first embodiment, the operation of selecting a necessary area from each camera image may also have its modes changed depending on the type of a synthesized image to be produced by the image processing section 20B. In that case, every time the mapping tables for use in image synthesis are changed, the area specifier 290 should newly obtain the area data representing the areas necessary for the image synthesis and then transmit it to the selectors 140 for the re-

spective cameras 110 through the transmission line 15.

Alternatively, area data sets, corresponding to the respective mapping tables, may also be stored beforehand on a ROM, for example, provided for the area specifier 290. In  
5 that case, the selection signal should also be input to the area specifier 290 so that the area specifier 290 can change the area data sets when the mapping tables are changed in response to the selection signal. Then, there is no need to perform the process step of newly obtaining the area data every  
10 ry time the mapping tables are changed.

As another alternative, the selector 140 may also include a memory for pre-storing the area data sets, corresponding to the respective mapping tables, thereon. Then, every time the mapping tables are changed, the image processing section 20B  
15 has only to send the ID of the mapping table newly selected to the selectors 140. Alternatively, instead of getting the mapping table ID sent from the image processing section 20B, the selection signal may also be input to the respective selectors 140 in the camera section 10B so that the selectors 140 can  
20 change the area data sets every time the mapping tables are changed.

It should be noted that the third embodiment of the present invention is combinable with the second embodiment. That is to say, the readout controller 270 and sync signal generator  
25 tor 280 of the second embodiment may be added to the image

processing section 20B shown in FIG. 15 to control the camera image readout order in a similar manner.

In the foregoing embodiments, the resolution or area specifier 260 or 290 is included in the image processing section 20, 20A or 20B. Alternatively, the camera section 10 or 10A may include means equivalent to the resolution specifier 260 and the camera section 10B may include means equivalent to the area specifier 290.

In that case, every time the types of synthesized images to be produced are changed, the image processing section 20, 20A or 20B should transmit the data stored on the mapping table 220 newly selected to the camera section 10, 10A or 10B by way of the transmission adapter 250 and transmission line 15. Also, the camera section 10, 10A or 10B may also include a memory for pre-storing the resolution or area data sets, corresponding to the respective mapping tables, thereon. Then, every time the types of synthesized images to be produced are changed, the image processing section 20, 20A or 20B has only to send the ID of the mapping table newly selected to the camera section 10, 10A or 10B. Alternatively, instead of getting the mapping table ID sent from the image processing section 20, 20A or 20B, the selection signal may also be input to the camera section 10, 10A or 10B so that the camera section 10, 10A or 10B can change the resolution or area data sets every time the mapping tables are changed.

Like the resolution or area specifier 260 or 290, the readout controller 270 and sync signal generator 280 of the second embodiment may also be included in the camera section 10, 10A or 10B.

5 In the foregoing embodiments, the camera images taken by the cameras are all supposed to be used for image synthesis. However, only some of those camera images might be necessary for image synthesis. In that case, the mode of cutting down the amount of data transmitted, including specifying the resolu-  
10 tions or areas required, should be selected for only those camera images necessary for image synthesis.

Also, in the foregoing embodiments, the compressors 120 or selectors 140 are provided as image data cutdown means for all the cameras. However, the compressors 120 or selectors  
15 140 may be provided for just some of the cameras. That is to say, some cameras may have the compressors 120 or selectors 140 and the other cameras may have no compressors 120 or selectors 140. In that case, the mode of cutting down the amount of data transmitted, including specifying the resolu-  
20 tions or areas required, should be selected for only those cameras that do include the compressors 120 or selectors 140 and are necessary for image synthesis.

In the foregoing description, the monitoring system of the present invention is supposed to be applied to vehicles.  
25 However, the present invention is equally applicable to any

other types of moving objects including airplanes, boats and ships. Furthermore, cameras for the inventive monitoring system may be placed on a still object to be monitored, e.g., shops, residences and showrooms. Moreover, the positions and  
5 number of cameras to be mounted are not limited to the illustrated ones.

Furthermore, part or all of the functions of the inventive monitoring system may be implementable by either dedicated hardware or software programs. It is also possible to use  
10 a storage or transmission medium that stores thereon a program for getting the inventive image processing executed by a computer either partially or entirely.

As described above, according to the present invention, image data, captured by respective cameras, has its amount cut  
15 down in a mode that has been selected in accordance with a correspondence between a synthesized image to be produced and the respective camera images. Then, the image data in the reduced amount is transmitted from the cameras to an image processing section by way of a transmission path. In this manner,  
20 the amount of image data to be transmitted can be cut down considerably without sacrificing the quality of the resultant synthesized image. As a result, the transmission path is implementable as a smaller number of less expensive transmission lines or even as a wireless path. That is to say, the trans-  
25 mission path is much easier to mount on a vehicle or requires

maintenance much less often. In addition, a buffer memory required for the image processing section can also have its storage capacity reduced greatly. The amount of image data to be transmitted can be cut down either by compressing the image data according to the resolutions that should be necessary for image synthesis or by removing the image data entirely but the areas necessary for the image synthesis.
